In 2025, the atmospheric CO₂ growth rate based on the globally averaged marine boundary layer (MBL) observations from the NOAA network fell to 2.06 ± 0.09 ppm yr⁻¹ after the record-high 3.76 ± 0.09 ppm yr⁻¹ in 2024 and below the 2015–2022 mean of 2.47 ppm yr⁻¹ (Fig. 1a) [1]. Both the satellite-based Growth Rates Using Satellite Observations (GRESO) estimates, derived from independent OCO-2 and GOSAT observations [2], and our OCO-2-constrained flux inversions showed a marked decline in the whole-atmosphere CO₂ growth rate between 2024 and 2025, from 3.40 ± 0.09 to 1.96 ± 0.09 ppm yr⁻¹ and from 3.63 ± 0.05 to 2.15 ± 0.05 ppm yr⁻¹, respectively. The monthly GRESO record shows that this decline developed mainly from late 2024 into early 2025, following the decay of the 2023/24 El Niño and coinciding with a moderation of the exceptional positive global temperature anomaly, with monthly CO₂ growth remaining comparatively low through much of 2025 (Fig. 1b). The MBL CO₂ growth rate declined by 45.2% between 2024 and 2025, even as global fossil CO₂ emissions were estimated to increase by 0.7% to 10.38 GtC yr⁻¹ in 2025 [3,4]. This contrasting evolution points to a recovery of terrestrial carbon uptake after the pronounced land sink weakening documented in 2024 [3,5]. Here, we present a low-latency global and regional carbon budget for the year 2025, using top-down inversions and bottom-up models, with a new satellite-driven biophysical model BESS [6]. We assess the contributions of land and ocean carbon uptake to the sharp decline in atmospheric CO₂ growth and quantify the magnitude and spatial pattern of land sink recovery following the 2023–2024 weakening.

We combined bottom-up land flux estimates from three dynamic global vegetation models (DGVMs), JULES, ORCHIDEE-MICT and LPJ-EOSIM [7–9], with machine-learning emulators of the ocean biogeochemical models and data-driven air-sea products used in the Global Carbon Budget (GCB) 2025 [3,10], and top-down land and ocean flux estimates from four atmospheric inversion models (CAMS, CMS-Flux, CTE and GONGGA), using OCO-2 retrievals of total column CO₂ [11–14], which improves data coverage, particularly over the tropics, with a data release latency of about six weeks, providing better spatial resolution and earlier detection of flux anomalies than in situ networks. A riverine carbon transport correction was applied consistently to both land and ocean fluxes from all four atmospheric inversions. The DGVMs typically simulate fires with prognostic fire modules using population density, lightning ignitions, climate and simulated fuel moisture but have weaknesses in capturing extreme forest fires and tropical forest degradation and deforestation fires. Hence, for the two DGVMs that simulated fire (ORCHIDEE-MICT and LPJ-EOSIM), we subtracted their original fire emissions and then added the mean of the Global Fire Emissions Database (GFED4.1s) [15] and the Global Fire Assimilation System (GFAS) [16] for the period 2010–2025 to all three DGVMs. Our approach allows a rapid diagnosis of the most recent changes in the global carbon cycle although we use the ERA5 climate forcing for DGVMs in this study instead of CRU-JRA in the GCB protocol, which has a time latency of around one year. Net land uptake is defined here as the sum of non-fossil land CO₂ fluxes including photosynthesis, respiration, fire and land-use change emissions.

The global carbon budget in 2025

Fig. 1c shows the bottom-up carbon budget, obtained by combining the average fossil emissions estimated by Carbon Monitor and previous projections of the Global Carbon Budget 2025 [3,4] with our bottom-up estimates of net land and ocean carbon fluxes. Fig. 1d shows the top-down carbon budget based on the mean of the four OCO-2 inversions. Global fossil CO₂ emissions were 10.38 GtC yr⁻¹ with a range of 10.34 – 10.42 GtC yr⁻¹ from our two estimates. In the bottom-up budget, the DGVMs estimated a net land sink of 2.04 ± 0.24 GtC yr⁻¹ in 2025, a marked reversal from the net land source of 0.98 ± 0.51 GtC yr⁻¹ in 2024. In the top-down budget, the four atmospheric inversions

estimated a net land sink of 2.68 ± 0.20 GtC yr⁻¹ in 2025, compared with only a small sink of 0.08 ± 0.51 GtC yr⁻¹ in 2024. Averaging the bottom-up and top-down estimates gives a global net land sink of 2.36 ± 0.16 GtC yr⁻¹ in 2025. This represents a strengthening of 2.81 ± 0.31 GtC yr⁻¹ from 2024, with the 2025 sink 0.71 ± 0.13 GtC yr⁻¹ stronger than the 2015–2022 mean. The ocean CO₂ uptake for 2025 was 3.11 ± 0.36 GtC yr⁻¹ (our ocean flux emulators: 3.15 ± 0.65 GtC yr⁻¹, inversions: 3.06 ± 0.32 GtC yr⁻¹), similar to the 2024 mean. The bottom-up budget imbalance, defined as fossil emissions minus the sinks estimated by bottom-up models and the observed CO₂ growth rate, is 0.81 ± 0.69 GtC yr⁻¹ using the growth rate of MBL stations and a conversion factor of 2.124 GtC per ppm. As expected, the top-down budget closed to within 0.07 ± 0.26 GtC yr⁻¹ using the atmospheric accumulation implied by the inversions. The contrasting changes in land and ocean uptake indicate that the rebound of the terrestrial sink is the dominant carbon budget change associated with the sharp decline in atmospheric CO₂ growth in 2025.

Regional carbon flux anomalies in 2025

To gain insights into which regions contributed to the recovery of the land sink in 2025, we analyzed quarterly spatial patterns of land and ocean CO₂ flux anomalies from the bottom-up models and OCO-2 inversions, using 2015–2022 as the reference period. At the global scale, ocean uptake remained close to the 2015–2022 mean, in contrast to the much larger change in the land sink. The quarterly land and ocean flux anomalies are shown in Fig. S1, and their relationship with terrestrial water-storage anomalies is displayed in Fig. S2.

Over the ocean, both the emulator ensemble and the inversions indicated slightly stronger global carbon uptake relative to the 2015–2022 mean, with sink anomalies of 0.26 ± 0.22 and 0.06 ± 0.31 GtC yr⁻¹, respectively (Fig. S1). The clearest common regional signal was stronger uptake in the Southern Ocean, defined following the RECCAP2 ocean regional mask, with anomalies of 0.11 ± 0.10 GtC yr⁻¹ in the emulators and 0.12 ± 0.16 GtC yr⁻¹ in the inversions. The largest regional difference occurred in the Pacific Ocean, where the emulator ensemble indicated a small sink anomaly of 0.04 ± 0.09 GtC yr⁻¹, whereas the OCO-2 inversions indicated a source anomaly of 0.09 ± 0.17 GtC yr⁻¹ relative to the reference mean.

Over the land, the regional net CO₂ flux anomalies in Fig. S1 showed a marked recovery of tropical carbon uptake in 2025. At the ensemble-mean level, tropical lands shifted from net CO₂ sources in 2024 to net sinks in 2025, from 1.70 ± 0.28 to 0.85 ± 1.23 GtC yr⁻¹ in the DGVMs and from 1.35 ± 0.79 to 0.48 ± 0.67 GtC yr⁻¹ in the inversions. Relative to the 2015–2022 mean, the 2025 tropical land flux was a stronger sink by 0.32 ± 1.19 GtC yr⁻¹ in the DGVMs and 1.08 ± 0.44 GtC yr⁻¹ in the inversions, although the larger spread among DGVMs indicates greater uncertainty in the magnitude of the modelled tropical rebound. Both approaches showed enhanced uptake across large parts of Africa and northern Eurasia, while larger differences remained over Latin America, East Asia and North America (Fig. S1). In the Northern Hemisphere extratropics ($>23.5^\circ\text{N}$), the DGVMs retained a source anomaly of 0.19 ± 1.21 GtC yr⁻¹ in 2025 relative to 2015–2022 whereas the inversions indicated a sink anomaly of 0.28 ± 0.38 GtC yr⁻¹.

Over the tropical lands, the quarterly anomalies indicate a different timing of recovery between the two approaches (Fig. S1). The DGVMs produced weak source anomalies during the first half of 2025 and shifted toward stronger than normal uptake during the second half of the year, whereas the inversions indicated enhanced tropical uptake throughout 2025. Over tropical South America, source anomalies estimated by the inversions persisted in parts of the region during JFM 2025 following the

severe drought and fire-related carbon losses of late 2024 [5], but weakened thereafter. The inversions showed a broader shift toward sink anomalies from AMJ 2025 onward, whereas the DGVMs retained a more spatially heterogeneous mixture of source and sink anomalies (Fig. S1). In contrast, Africa showed widespread regions of enhanced uptake in both approaches. The spatial distribution of the 2025 land flux anomalies also covaried with terrestrial water storage from GRACE, with wetter conditions frequently coinciding with enhanced CO₂ uptake and drier conditions with reduced uptake in both the DGVMs and inversions (Fig. S2).

To determine whether the 2025 sink rebound occurred where the land sink had previously weakened, we quantified recovery in grid cells where the mean 2023–2024 sink loss relative to 2015–2022 exceeded 10 gC m⁻² land yr⁻¹ (Fig. 1e,f). Such a pattern could reflect short-term memory in the land carbon cycle, for example through the refilling of fast pools such as litter and foliage that were depleted in 2023–2024. Recovery of 100% denotes a return to the 2015–2022 mean flux, whereas values above 100% indicate that land uptake in 2025 exceeded the reference mean. Within areas that experienced substantial carbon sink losses in 2023–2024, about 80% of the land area showed some recovery in 2025 in both approaches (80.1% in the DGVMs and 80.0% in the inversions). Overall recovery reached 87.3% in the DGVMs and 99.5% in the inversions. Recovery was strongest in the tropics, where it exceeded 100% in both approaches (DGVMs: 106.4%; inversions: 116.4%), but remained weaker in the Northern Hemisphere extratropics (DGVMs: 59.6%; inversions: 90.7%). Nearly half of the substantial-loss area showed recovery exceeding 100% (48.5% in the DGVMs and 48.9% in the inversions). Thus, the global rebound reflected incomplete recovery in some regions but land uptake exceeding the 2015–2022 mean in others, rather than a spatially uniform recovery.

Together, these results show that the sharp decline in atmospheric CO₂ growth rate in 2025 was driven primarily by a strong rebound in terrestrial carbon uptake, but that this recovery was spatially uneven. Tropical recovery generally restored or exceeded the reference sink strength, whereas recovery remained incomplete across northern extratropical regions. Due to the recovery being primarily in storage in fast turnover pools, i.e., litter and foliage, the variability in atmospheric CO₂ growth is likely to remain with terrestrial systems as the primary driver. The strong global land sink in 2025 therefore reflected a broad recovery, with uptake exceeding the 2015–2022 mean globally despite incomplete recovery in parts of the northern extratropics.

Data availability

The data from Global Carbon Budget 2025 are available at <https://globalcarbonbudget.org/datahub/the-latest-gcb-data-2025/>. The OCO-2 retrievals are available at disc.gsfc.nasa.gov/datasets?page=1&keywords=OCO-2. NOAA/GML CO₂ data are available at <https://gml.noaa.gov/ccgg/trends/>. The Carbon Monitor fossil emissions dataset is available at carbonmonitor.org. The GFED 4.1s fire emissions dataset is available at geo.vu.nl/~gwerf/GFED/GFED4/. The GFAS fire emissions dataset is available at atmosphere.copernicus.eu/global-fire-monitoring/. The ERA5 monthly averaged data is available at cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels-monthly-means?tab=overview. The GRACE/FO TWS data used in this study are available at www2.csr.utexas.edu/grace/RL06_mascons.html.

Author contributions

Fig. 1 Atmospheric CO₂ growth rate from 1959-2025, global carbon budget from 2010-2025 and spatial recovery of the 2023-2024 land sink losses in 2025. (a) Annual atmospheric CO₂ growth rates from globally averaged marine boundary layer observations (MBL, blue bars), the Mauna Loa station (MLO, dark blue squares), OCO-2 constrained atmospheric inversions (brown squares), and the Growth Rates Using Satellite Observations approach (GRESO, orange squares). GRESO values are based on GOSAT for 2010–2014 and on the mean of independently derived OCO-2 and GOSAT estimates from 2015 onward. (b) Monthly GRESO CO₂ growth rate (black line), Oceanic Niño Index (ONI; red and blue shading for El Niño and La Niña conditions, respectively), and global surface temperature anomaly (orange line, 5-month running mean) from 2015 to 2025. (c) Global bottom-up

CO₂ budget obtained from fossil CO₂ emissions, net land CO₂ flux from three DGVMs, ocean CO₂ uptake from the low latency ocean emulator ensemble, and atmospheric CO₂ accumulation derived from MBL observations. The red curve is $-1 \times$ fossil emissions and the difference between the bars and this curve is the imbalance of the bottom-up budget. (d) Global top-down CO₂ budget obtained from fossil CO₂ emissions and four atmospheric inversions constrained by OCO-2 observations. Atmospheric accumulation is derived from the inversion ensemble; orange squares show the corresponding budget sum using the independent GRESO atmospheric growth rate estimate. Spatial recovery in 2025 of the mean 2023–2024 net land CO₂ sink loss relative to the 2015–2022 baseline, estimated from the three DGVMs (e) and four atmospheric inversions (f). Recovery is evaluated only where the mean 2023–2024 sink loss exceeds 10 gC m⁻² land yr⁻¹. Brown indicates no recovery, yellow 0–50% recovery, light green 50–100% recovery, and dark green >100% recovery. A recovery of 100% denotes a return to the 2015–2022 mean flux, whereas values >100% indicate that the 2025 land sink exceeded the reference mean. Grey land areas did not meet the substantial loss threshold or were excluded from the recovery analysis.

Fig. S1 Net land and ocean CO_2 flux anomalies for each quarter in 2025 compared with the 2015-2022 average for bottom-up models (left column) and the OCO-2 inversions (right column). Positive values represent increased flux from the atmosphere to the land or ocean (carbon sink).

Fig. S2 Bivariate plots showing co-variations between net land flux anomalies from (a) DGVMs and (b) inversions and total water storage anomalies from the GRACE satellites in 2025. Green areas show wetter anomalies coincident with more CO₂ uptake, and magenta areas show drier anomalies that are coincident with reduced CO₂ uptake.
